(Received 15 August 2012; revised manuscript received 24 June 2013; published 6 January 2014)

The seemingly extraordinary electronic transport observed in epitaxial films of LaAlO$_3$ (LAO), LaTiO$_3$ (LTO), and related perovskites grown on TiO$_2$ terminated (001) SrTiO$_3$ (STO) has taken central stage in condensed matter physics research in recent years. 1–4 The origin of two-dimensional electron gas (2DEG), whose mobility and carrier density depend strongly on growth temperature and oxygen partial pressure,1–3 and which can be modified further by ultraviolet light 2 and electric field,5 has been attributed to interfacial factors such as atomic relaxation, electronic reconstruction, cation intermixing, and/or creation of oxygen vacancies.6 The electronic properties of such interfaces have been studied extensively owing to unusual charge transport,1,7 magnetism,8–10 two-dimensional superconductivity,11–13 and quantum oscillation in the conductivity.14,15 While several types of oxide overlayers show unusually large interfacial conductivity,16,17 the common denominator in all these cases is STO, which even without any overlayer, but subjected to subtle surface treatments, can show fascinating 2D electronic behavior.18,19

Departing from the commonly used approach of growing oxide overlayers, here we show a similar electronic transport realized at the interface of a half-metallic Heusler alloy and STO. The Heusler compounds have generated considerable interest in recent years due to a myriad of properties encompassing half-metallicity, shape memory effect, thermoelectricity, superconductivity, and topologically inhibited conducting states.20 While our discovery of a highly conducting interface between Heusler alloys and STO can have potential technological applications, the fundamental mechanism for the origin of such a state brings into question the several interpretations given for 2DEG previously.

The thin films of Co-based full-Heusler alloys such as Co$_2$FeSi (CFS) and Co$_2$MnSi (CMS) have been grown on a variety of semiconductors and oxide dielectrics.21–25 The substrates used in present study were (001) LAO, MgO, NdGaO$_3$ (NGO), and STO, whose face diagonal matches quite well with the lattice parameter ($\approx0.565$ nm) of CM(F)S. We have deposited a large number (over 70) of highly ordered single phase thin films of CM(F)S under various growth environments using a pulsed laser ablation technique.26 The growth rate of a 0.0065 nm per laser pulse allows the synthesis of smooth and uniform epitaxial films.

We begin by showing the most striking result, which compares the resistivity $\rho(T)$ of CFS films grown on LAO, MgO, NGO, and STO in Fig. 1(a). The resistivity of the films on LAO, MgO, and NGO falls by only 25% of its value at 300 K as we approach 5 K. Contrary to this, the film on STO has a very low residual resistivity ($\rho_0 \approx 0.08 \mu\Omega\text{cm}$); a parameter which gives a measure of the electron scattering due to defects and impurities present in the system. Furthermore, the films on STO display giant values ($\approx1680$) of residual resistivity ratio (RRR). In comparison, the lowest reported $\rho_0$ so far for CMS films on any other substrate is $\approx16 \mu\Omega\text{cm}$.27 For single crystals, the $\rho_0$ is in the range of 1.5–3.0 $\mu\Omega\text{cm}$.27,28 Similarly, the best RRR reported for the films and single crystals is limited to only 5–6.27,28 Since STO is prone to reduction in vacuum at elevated temperatures ($>850 ^\circ\text{C}$), which may render it conducting,29 it is important to rule out this possibility during the film growth. A bare (001) STO substrate treated under the same conditions as used for the film growth shows an insulating behavior (sheet resistance $>1 \text{M}\Omega$). Moreover, the maximum temperature to which the substrates were exposed was 600 $^\circ\text{C}$, where the reduction of STO is highly unlikely.

Furthermore, we recover the insulating nature of STO after etching off the films with dilute HNO$_3$, which shows that the observed transport property is related to the regions near the film-substrate interface. We have compared the resistivity of CFS/STO film with CFS single crystal and LAO/STO 2DEG systems for further insights [Fig. 1(b)]. Clearly the $\rho_0$ is an order less than that for the single crystal, while RRR for CFS/STO is comparatively quite large. Although such high RRR is also observed for reduced STO29 and highly oxygen deficient LAO/STO,3 the $\rho_0$ in such systems is two orders of magnitude higher. The x-ray diffraction studies on the films show a high degree of crystallographic ordering with root mean square interface roughness $\leq1 \text{nm}$.26 Moreover, their saturation magnetic moments are in accordance with the Slater-Pauling rule even for the thinnest film. All these results
suggest that the observed charge transport is not of structural or magnetic origin.

We believe that the explanation for this extraordinary electronic transport lies in the physics and chemistry of the film-substrate interface, which has been examined by scanning transmission electron microscopy (STEM) imaging (Fig. 2). The CFS/STO interface as shown in Fig. 2(a) is sharp and coherent with an FeSi layer of CFS connecting with a TiO₂ layer of STO substrate. Interestingly, the contrast of the FeSi layer at the interface (indicated by the green arrow) is slightly stronger than that in the film implying a higher electron density at this layer, which may be due to some Sr at the Fe sites. Moreover, the contrast of the TiO₂ and SrO layers at the interface (indicated by the magenta and cyan arrows, respectively) is weaker than that in the substrate, suggesting that some Fe and Si may have diffused to these layers. The visible contrast in the O site of the SrO layer at the interface (indicated by the yellow arrow) also suggests replacement of O by Si at this site. Based on these observations, we infer a 0.78-nm-thick region of interdiffusion at the interface.

FIG. 1. (Color online) (a) The normalized resistance $R(T)/R(300 \text{ K})$ of 40-nm-thick CFS films on (001) oriented LAO, MgO, NGO, and STO grown in vacuum. (b) The resistivity of LAO/STO, oxygen deficient LAO/STO, reduced STO, CFS single crystal, and CFS (12 nm)/STO (present work). The thickness of conducting layer in the LAO/STO system is 10 nm while it is 0.5 mm for the film where the oxygen vacancies dominate the conduction.

However, the conductivity of STO doped with 3$d$-transition metal elements is quite low as compared to the conductivity value of $\sim 10^3 \Omega^{-1} \text{ cm}^{-1}$ at 300 K observed for CFS/STO films. For example, the 0.1 wt % Fe doped STO has a conductivity of $\approx 2 \times 10^{-6} \Omega^{-1} \text{ cm}^{-1}$ at 300 K. The electron energy loss spectra (EELS) as shown in Figs. 2(c) and 2(d) reveal a significant difference in the intensity of O prepeak (528 eV) relative to that of O main peak (535 eV) as a function of the distance from the interface (DFI), which indicates the transitions from O 1$s$ to unoccupied 2$p$ states and hybridized Ti-3$d$ states. While the intensity of O prepeaks at and near the interface (light blue to blue lines) is low, it increases when the DFI is larger than 1.9 nm (from orange line). The relative O prepeak intensity, defined as the intensity of O prepeak divided by that of O main peak, gradually increases until DFI = 1.9 nm and then becomes flat, which is suggestive of hole depletion at the interface [Fig. 2(e)]. This interfacial oxygen deficient region of thickness $\approx 1.9$ nm can lead to the formation of 2DEG at the CFS/STO interface. The oxygen vacancies in STO can be created due to interfacial redox reactions with the metallic components of CM(F)S layer. Such effects have been speculated at the interface between STO and other complex oxides with Al, Ti, Zr, and Hf elements. However, the oxidation of Fe grown on (001) STO is only observed above 800°C. We expect a similar threshold for the oxidation of Fe in CFS/STO.
other 3$d$ transition metals like Co and Mn. This only leaves the possibility of the redox reactions by Si. To verify such an effect, we have grown thin films of yet another Heusler compound Co$_2$FeAl on STO under the same conditions used for the growth of CM(F)S/STO.26 These samples show a RRR of only 1–2, which suggests that the Si is responsible for the formation of oxygen deficient region confined at the interface with attendant high mobility electron gas.

The possibility of such 2DEG is further strengthened from transport measurements on a series of films of varying thickness deposited on MgO and STO (Fig. 3). One would anticipate that the resistivity of thinner film should be greater than that of the thicker film due to enhanced surface scattering, strain induced defects, and/or the presence of electrically dead layers at the interface. Indeed, we observe such behavior in the films grown on MgO [Fig. 3(a)]. On the contrary, the $\rho(T)$ of the films on STO reduces with decreasing thickness [Fig. 3(b)], suggesting the presence of an electrically more conducting layer at the interface. A linear extrapolation of the $\rho(T)$ data [Fig. 3(c)] to $T = 0$ leads to the limiting resistivity $\approx 0.008 \, \mu \Omega \, \text{cm}$ of the interface at 10 K. We have estimated the conductivity of the interfacial layer in the framework of a simple parallel resistor model, which assumes an interfacial layer of thickness $t_i$ and the film with thickness $t$, while their respective conductivities are $\sigma_i$ and $\sigma_f$. The net effective conductivity is expressed as

$$\sigma = \sigma_f + \frac{t_i \sigma_i}{t}.$$  \hspace{1cm} (1)

The $\sigma_i$ can be estimated from the slope of the $\sigma$ vs $(1/t)$ curve if $t_i$ is known. Assuming the interfacial layer to be 1.9 nm as estimated before, we get a $\rho_i \approx 0.006 \, \mu \Omega \, \text{cm}$ at 10 K [Fig. 3(d)], which corresponds to sheet conductance of $G_s \approx 32 \, \Omega^{-1}$. In comparison, the reported values of $G_s$ for oxide interfaces are an order of magnitude lower. For example, a conductance of $\sim 10^{-3} \, \Omega^{-1}$ has been reported for LAO/STO$^{5,34}$ and LTO/STO.$^{12}$

The Hall resistance ($R_{xy}$) of CFS film on MgO [Fig. 4(a)] displays a characteristics anomalous behavior of a ferromagnet induced by a sharp rise of $R_{xy}$ till magnetic saturation. In contrast, for the film on STO, we observe a linear field dependence of $R_{xy}$ up to 14 T with no anomalous contribution. Figures 4(b) and 4(c) show the carrier concentration ($n$) and Hall mobility ($\mu_H$) of CFS/STO films, respectively. With decreasing thickness, a monotonic increase in $n$ is observed with a highest value of $3.3 \times 10^{21} \, \text{cm}^{-3}$ at 2 K for 12 nm film, which can be qualitatively explained by considering the parallel resistor model, where

$$n = \frac{\sigma^2}{e[\sigma_f \mu_f + \frac{1}{2} \sigma_i \mu_i]}.$$  \hspace{1cm} (2)

Here, $\mu_i$ and $\mu_f$ are the mobilities of the interfacial layer and the film, respectively. We can assume that $\sigma_f$, $\sigma_i$, $\mu_f$, and $\mu_i$ are independent of $t$ at a particular temperature. Under these conditions and $\sigma \sim 1/t$ [from Eq. (1)], we obtain $n \sim 1/t$, i.e., $n$ increases with decreasing thickness. The thickness independence of $\mu$ [Fig. 4(c)] implies that (1) $n \propto \sigma$ (or $1/\rho$), which can be seen in the inset of Fig. 4(a), and (2) the scattering due to impurities or defects does not play a dominant role in these films. We have estimated the electronic mean free path ($l$) to be 2–5 $\mu$m at 2 K from the observed values of $\mu_H$ and thus a very large Ioffe-Regel parameter ($k_f l \sim 12000–22000$).
n is almost independent of temperature for each thickness [Fig. 4(b)]. This is in contrast to the result in the LAO/STO system, where n decreases with decreasing temperature due to the carrier freezing at impurity sites.\textsuperscript{35} On the other hand, the $\mu_H$ decreases drastically with increasing temperature from a very large value of $\sim$20 000 cm$^2$ V$^{-1}$ s$^{-1}$ at 2 K. This indicates that the observed low $\rho_0$ and high RRR are due to a change in $\mu_H$ rather than in $n$. The $n \approx 1.2 \times 10^{27}$ cm$^{-3}$ and $\mu_H \approx 0.68$ cm$^2$ V$^{-1}$ s$^{-1}$ of CFS (30 nm)/MgO film are comparable to earlier reports.\textsuperscript{36} Another interesting feature of these data is relatively low values of $n$ for CFS/STO as compared to that for CFS/MgO [see Fig. 4(b)]. The high $n$ in the films on MgO has been attributed to the partially compensated Hall voltage by electronlike and holelike portions of Fermi surface. The high $\mu_H$ is relative to the interface barrier may be at work in addition to the interfacial STO near the interface. We believe that the electronic correlations also play a crucial role in these systems. Using the literature data of $\epsilon \approx 330$ at 300 K (and 24 123 at 4.2 K) for STO\textsuperscript{37} and the effective mass $m^* \approx 3m_e$,\textsuperscript{38} where $m_e$ is the electronic mass, we obtain the Bohr radius $a_B \approx 5.8$ nm at 300 K (and 425 nm at 4.2 K). These values are quite large compared to electron-electron separation ($\sim 1/n_i^{1/3}$) of $\approx 0.5$ nm, which suggests the electronic interactions are important for the understanding of these systems.

In summary, we have observed extraordinary electron transport in epitaxial Co$_2$MnSi and Co$_2$FeSi films on (001) SrTiO$_3$ with a low $\rho_0$, which is at least an order of magnitude smaller than the values reported in these compounds so far. The films show a giant RRR of $\approx 1680$ and $\mu_H$ as high as $\sim 20000$ cm$^2$ V$^{-1}$ s$^{-1}$ at 2 K. The STEM combined with EELS shows the presence of an oxygen deficient region confined within 1.9-nm-thick STO near the interface, where a two-dimensional high mobility electron gas appears to prevail. The thickness dependent study further establishes the presence of an electrically more conducting interfacial layer. The highly spin polarized character of electrons in Heusler alloys adds a magnetic dimension to the problem, which is potentially important for spintronics. Our results are expected to trigger research on the interfaces of several other intermetallics with SrTiO$_3$.
